Abstract

We have carried out computer simulations of the statics and dynamics of an isolated model polymer chain with excluded volume in a solvent acting as a heat bath. We find that the distribution function for the separation of a pair of beads scales as the number of beads $N$ to the power $\nu$ and that edge effects are small. The dynamical correlation functions, such as that of the end-to-end vector, scale as $N^{2\nu+1}$ with $\nu \approx 0.6$. The results of a dynamical lattice polymer model are shown to be consistent with the present results if one adjusts the time scales in such a way that the center of mass diffuses at the same rate in the two models. The relaxation of the stress tensor, is shown to be quite similar to that of the Rouse model. Finally, it is shown that edge effects are much more pronounced in the diffusive motion of the individual beads, there being a skin comprising about 30% of the total polymer, where bead motion is relatively quicker.
1. **Introduction**

When a solution of macromolecules is sufficiently dilute the interactions between polymer chains can be neglected.\(^1,^2\) A good model for this system then consists of one chain in a sea of solvent. We describe here some equilibrium and kinetic properties obtained by numerically simulating the dynamical evolution of such chains. A preliminary account of this work appeared earlier.\(^3\)

Computer calculations, and in particular Monte Carlo methods, have been used previously to find the equilibrium properties of a single chain, especially for lattice models. Our results are in agreement with other calculations in showing that when there are excluded volume interactions between elements of the chain, then the size of the chain grows as \(N^\nu\), where \(N\) is the number of beads and \(\nu \approx 0.6\). This agrees in turn with theories proposed by Flory and others \(^1,^2\) that the exponent should be universal \(^4\), independent of the details of the excluded volume interaction and are the same for lattice and continuum systems.

On the other hand, dynamical calculation of lattice models have not shown the same kind of agreement with theoretical predictions.\(^5\) The models used have subsequently been criticised\(^6\) on the grounds that a lattice cannot faithfully represent the dynamics of a real polymer in which small bending and stretching motions may be important.
We therefore decided to carry out direct simulations of the dynamics of such a model chain with excluded volume in a heat bath representing a solvent. For the sake of simplicity and tractability we have neglected in this study the hydrodynamic interactions between different parts of the polymer. This interaction does not have any effect on the equilibrium properties of the chain and its effect on the kinetics, while very important, is separable, in principle, from the effects of the excluded volume we shall study here.\textsuperscript{7,8,9}

Since the appearance of our earlier report\textsuperscript{3} additional computer studies of continuous polymer chains, dealing primarily with equilibrium properties have appeared.\textsuperscript{10,11} There has also been a new study by Kranbuehl and Verdier\textsuperscript{12} of the kinetics of chains with excluded volume on a lattice in which additional degrees of mobility were permitted. This brought their relaxation times for $N < 50$, into agreement with our values but still left the relaxation times for larger chains slower than ours. It is our belief that this is again due to the limited repertoire of steps available on the lattice. We shall show, that when time is consistently defined in the two models, their results agree with ours, even for large chains.
2. Description of Model

For our present investigation we have chosen the 'bead-spring' model to represent the polymer chain. The chain contains \( N \) beads with coordinates \( r_i : 1 \leq i \leq N \). Successive beads are connected by harmonic springs. A repulsive, short range, excluded volume interaction \( \phi(r) \) acts between all pairs of beads. The total potential energy of the chain is:

\[
U(R) = \sum_{i=1}^{\frac{1}{2}} \kappa (r_i - r_{i+1})^2 + \sum_{i<j} \phi(|r_i - r_j|) \tag{2.1}
\]

A repulsive Lennard-Jones 6-12 potential was chosen to represent the excluded volume interaction:

\[
\phi(r) = \begin{cases} 
4\varepsilon \left[ \left( \frac{\sigma}{r} \right)^{12} - \left( \frac{\sigma}{r} \right)^6 + \frac{1}{4} \right] & r \leq r_c \\
0 & r \geq r_c 
\end{cases} \tag{2.2}
\]

where \( r_c = 2^{1/6} \sigma \). This potential is continuous and has a continuous first derivative, but is stiff enough for small \( r \) that the effective excluded volume depends only weakly on \( \varepsilon \). On the other hand \( \varepsilon = 0 \) or \( \sigma = 0 \) corresponds to the Rouse model, \( 1, 13 \) i.e. to an ideal chain.

The energy \( U(R) \) in (2.1) is to be thought of as modeling the effective, purely repulsive, interactions between polymer segments in a good solvent. \( 1, 2 \)

The equilibrium distribution of a chain in such a solvent is \( z^{-1} \exp(-\beta U(R)) \), with \( \beta \) a parameter playing the role of a reciprocal temperature. The essential feature of universality is
that many properties of the chain are, for large \( N \), independent of the details of \( U(R) \).

We have chosen our units of length to be \( \sigma \) and let \( \beta \kappa = 2 \) and \( \beta \varepsilon = 0.1 \). With these parameters the average bead separation in equilibrium is 1.45. While it is possible for two sections of the chain to cross, such events are very unlikely and presumably do not affect the results significantly.

Following the work of Kirkwood and Rouse\(^7,13\) we assume that the velocity of the polymer is proportional to the forces acting on it at any time; this is the high viscosity limit in which inertial terms are neglected. Neglecting also hydrodynamic forces we then have for the velocity of the \( j^{th} \) bead at time \( t \),

\[
\mathbf{v}_j(t) = -\beta D \mathbf{v}_j U(R) + \mathbf{w}_j(t) \tag{2.3}
\]

Here \( \beta \) is the reciprocal temperature of the solvent, \( D \) is the diffusion constant of a monomer, \( W \) is a Gaussian fluctuating "Langevin force" (due to the solvent) with mean \( \langle W_j(t) \rangle = 0 \), and covariance \( \langle W_i(t_1) W_j(t_2) \rangle = 6D\delta(t_1 - t_2)\delta_{ij} \). Eq. (2.3) leads to the Smoluchowski equation\(^{14}\) for the time evolution of the polymer probability density \( f(R,t) \),

\[
\frac{\partial f}{\partial t} (R,t) = D \sum_{j=1}^{N} \nabla_j \left[ \mathbf{v}_j f(R,t) + \beta f(R,t) \mathbf{v}_j U(R) \right] \tag{2.4}
\]
The solution of (2.4) approaches equilibrium as \( t \to \infty \):

\[
f(R,t) + Z^{-1} \left[ \exp -\beta U(R) \right],
\]

(2.5)

3. **Computational Method**

The stochastic process described by (2.3) (or equivalently the solution of the diffusion equation (2.4)) was simulated by a novel Monte Carlo scheme.

A simple simulation method would be to displace every particle at each time step by an amount proportional to the sum of the internal force and the random force. That is:

\[
r_i(t+\tau) = r_i(t) - \tau \beta D \nabla_i U + \chi_i \tag{3.1}
\]

where \( \langle \chi_i \chi_j \rangle = 6 D \tau \). This method is not useful in the presence of strong excluded volume forces since if an overlap occurs (\( |r_i - r_j| \) is small for some pair \( ij \)) the internal force on particles \( i \) and \( j \) in the next time step will be very large and they could be thrown far from the polymer. The time step \( \tau \) would have to be exceedingly small to alleviate this problem. A systematic way is needed of rejecting those moves where the potential energy increases significantly.

To achieve this goal, let us first define the Green's function for the process: \( G(R_0,R,t) \) is the probability density for the polymer to diffuse from the point \( R_0 \) to the point \( R \) (\( R_0 \) and \( R \) are vectors in the \( 3N \) dimensional configuration space) in time \( t \). In other words \( G \) is the solution of eq. (2.4) with boundary
conditions:

\[ G(R_0, R, 0) = \delta(R_0 - R) \]  \hspace{1cm} (3.2)

Knowledge of the Green's functions for time \( \tau \) is sufficient to simulate the diffusion process in steps of \( \tau \) since:

\[ f(R, t + \tau) = \int dR_0 \ f(R_0, t) \ G(R_0, R, \tau) \]  \hspace{1cm} (3.3)

An approximation, exact if \( \nabla U \) is constant, is

\[ G_0(R_0, R, \tau) = (2\pi D\tau)^{-3N/2} \exp \left[ -\frac{(R - R_0 + \tau \nabla U(R_0))^2}{4D\tau} \right] \]  \hspace{1cm} (3.4)

Variation of \( \nabla U \) in (3.4) may lead to unphysical overlaps which can be avoided if \( G_0 \) is altered to satisfy the detailed balance condition obeyed by the exact Green's function,

\[ \exp [-\beta U(R_0)] \ G(R_0, R, t) = \exp [-\beta U(R)] \ G(R, R_0, t) \]  \hspace{1cm} (3.5)

In our simulation algorithm, we use the standard Metropolis rejection technique, more familiar with equilibrium simulations but equally applicable here, to enforce (3.5). Our simulation reads:

1) Start from a configuration \( R = (r_1, \ldots, r_N) \). Permute the integers randomly. This permutation is kept fixed until all particles have been moved once.

2) Sample a new position \( r_i' \) for particle \( i \) from equation (3.1) where only \( \chi_i \) is nonzero.

3) Accept this move with probability \( q(R, R') \) where:
\[ q(R,R') = \min \left[ 1, \frac{e^{-\beta U(R')} G_0(R',R,T)}{e^{-\beta U(R)} G_0(R,R',T)} \right] \] (3.6)

This acceptance probability is constructed so that the transition probability density, \( q(R,R') G_0(R,R',T) \), satisfies the detailed balance condition. This assures that \( f(R,t) \) obtained from the simulation satisfies (2.5).

4) If the move is accepted, the coordinates of that particle, \( \mathbf{r}_i \), are replaced by their new values, viz. \( \mathbf{r}_i' \). If not the old values are retained.

5) Steps 1) through 4) are performed for each particle in the succession given by the random permutation. Time is advanced by an amount \( \tau \) after each particle has had a trial move.

Because time advances whether or not the particle move is accepted, all diffusion processes will be slowed down by an amount proportional to the rejection ratio. In our simulations the time step \( \tau \) is kept small enough so that the rejection ratio is about 10%. With this time step it is reasonable to assume that all slow diffusive motions will be slowed down by the same factor. We can determine this scale factor since the diffusion of the center of mass can be calculated exactly from the Smoluchowski equation. It is given by

\[ \int dR \, G(R_0,R,t) \left[ \mathbf{z}(R) - \mathbf{z}(R_0) \right]^2 = 6D \tau / N \] (3.7)

where \( \mathbf{z} = \frac{1}{N} \sum_{i=1}^{N} \mathbf{r}_i \) is the center of mass. For \( \tau = 0.01 \) the
rejection ratio varied from 8.5% at \( N = 5 \) to 11.2% at \( N = 63 \). The slowing down of the center of mass varied from 6% at \( N = 5 \) to 7% at \( N = 63 \). All times reported below and shown in the figures have been scaled by this amount (0.94).

The computations of the force and potential are done efficiently with the use of near neighbor tables. At the start of the calculation a list of all the pairs \( ij \) with \( |x_i - x_j| < r_c + 2\Delta \) is constructed. \( \Delta \) is a constant which may be chosen to minimize the computer time required. Only distances for pairs in this list need be computed. The list is renewed when \( \max[x_i(t') - x_i(t)]^2 > \Delta \). Because the excluded volume potential keeps the polymer stretched out and because diffusion times are slow this neighbor scheme is very efficient for large polymers. However, as we shall see, all the diffusion times scale as \( N^{2.2} \) and since the computation effort per move increases as \( N \), the computer time needed to simulate a fixed number of relaxation times is proportional to \( N^{3.2} \). This limits the size of polymers which can be simulated by this scheme on present computers to approximately 100.

It is possible to generalize the above method to include a hydrodynamical interaction matrix (the Oseen tensor). Then the random forces in equation (3.1) would become correlated. This increases the computational effort considerably and has only been attempted for small chains (\( N = 10 \)). Those results will not be reported here.

4. Static Properties of a Single Polymer

In this section we present various static properties of an
isolated polymer chain emphasizing the various ways in which the scaling behavior of lengths manifests itself. We assume implicitly that there exists a well defined limiting behavior for very large polymers and that chains of finite length approximate this behavior when \( N \) is sufficiently large \(^{1,2}\).

4.1. Size-scaling

The customary way of demonstrating the scaling behavior of polymers is to plot the mean squared end to end distance versus the number of units in the polymer chain. Such a plot is shown in figure 1 for polymers with \( N = 5 \) to \( N = 63 \). We have fitted these numbers with a simple power law and find:

\[
< R^2_{1N} > \equiv \langle (r_1 - r_N)^2 \rangle \approx (0.92 \pm 0.02) a^2 (N-1)^{1.21 \pm 0.03} \tag{4.1}
\]

where \( a^2 = 2.1 \) is mean square link length in our units.

The radius of gyration is also plotted in figure 1 and obeys a similar relationship:

\[
G^2 = \frac{1}{N} \sum_{i=1}^{N} \langle (r_i - \bar{r})^2 \rangle \approx (0.11 \pm 0.05) a^2 (N-1)^{1.12 \pm 0.02} \tag{4.2}
\]

where \( \bar{r} \) is the center of mass of the chain. A more detailed analysis of computer results on a model chain with fixed links of length \( a \), and excluded volume interaction of the same form as ours, was made by Webman et al.\(^{10b} \). By taking explicitly into account the finite \( N \) corrections to the asymptotic power law they obtained:

\[
< R^2_{1N} > = a^2 (N-1)^{1.2} (1 - 0.5 a^{-1.8} N^{-0.2})
\]
Shown in Figure 2a are the mean values of \( \sqrt[\frac{1}{2}]{R_{ij}^2} = \sqrt{(r_i - r_j)^2} \) against \((i + j)/N\), the chemical center of the pair. The lines connect points of constant \(i-j\); they are lines of constant chemical distance. The tip of the tree represents the end to end distance squared and the base the nearest neighbor distances. The approximately constant value of \( R_{ij}^2 \) along the lines is a clear indication that the mean distance between two polymer beads is primarily a function of the chemical distance and independent of the placement of the beads within the chain. The slight bending of the branches halfway up the tree indicates that there are edge effects of the order of a few percent. The end of the polymer chain is typically surrounded by fewer polymer beads; thus it feels a smaller excluded volume force, and it has more freedom to bend than would a bead in the center of the chain. Also plotted in Figures 2b,c,d are \( R_{ij}^{n} \) for \( n = -1, 4, 6 \). Note that these graphs show the same behavior as \( n = 2 \). This indicates that the distribution of the \( R_{ij} \)'s is a universal function of \( R_{ij}/R_{ij}^{\frac{1}{2}} \) for long chains. We have checked the behavior of this tree as \( N \) changes and found that in appropriate reduced units, it has the same shape; we have not studied the effect of different potentials as a direct observation of universal behavior (see however Webman et al 10b and references therein).

4.2 Characteristic Shape

The average shape of a chain is another quantity which should be independent of the size of the chain. The simplest information about the shape is contained in the moment of inertia tensor defined by

\[
T_{ab} = \frac{1}{N} \sum_{i=1}^{N} (r_i - Z)_a (r_i - Z)_b
\]

\( a, b = 1, 2, 3 \)  \hspace{1cm} (4.3)
The eigenvalues of this tensor, $T_i$, are measures of the instantaneous width of the polymer in the three orthogonal principle axes, ordered so that $T_1^2 \leq T_2^2 \leq T_3^2$. Note that the sum of the three eigenvalues equals the radius of gyration. The average values of $T_i^2/G^2$, for $i=1$, and 2 are given in Table 1. Note that they are independent of the number of beads and in fact are almost identical with the equivalent ratios found in computer simulations of the self avoiding random walk on a lattice. These results indicate that the polymer is typically shaped like a highly elongated ellipsoid of inertia with the average principle axes being in the ratio of 1:1.8:4.0. For the non-self-avoiding random walk the corresponding ratios are 1:1.64:3.42.

4.3 Correlation functions

The two particle correlation function defined as,

$$g_{ij}(r) = \langle \delta(|\mathbf{r}_i - \mathbf{r}_j| - r) \rangle. \quad (4.4)$$

contains a wealth of information about the static properties of polymers. For example, the $n^{th}$ moment of this probability density is just $\langle R_{ij}^n \rangle$ defined above. As indicated earlier the approximate scaling behavior of the moments implies that this function should scale as

$$g_{ij}(r) \approx \langle R_{ij} \rangle^{-3} \hat{g}(r/\langle R_{ij} \rangle) \quad (4.5)$$

where $\hat{g}(r)$ is a universal function independent of $i,j$, and $N$. We have computed this scaled function using the configurations from our simulations. In order to increase the statistical accuracy we have averaged over all pairs with constant chemical distance, $|i-j|$. 
Define:

\[ g_m(r) = \frac{1}{N-m} \sum_{i=1}^{N-m} g_{i,i+m}(r) \]  

(4.6)

Plotted in figure 3 is \( \ln(R_m^3 g_m(r)) \) versus the scaled squared distance \( r^2/<R_m^2> \) for a 63 bead chain. The Gaussian chain appears as a straight line in this plot. There are small but significant changes with \( m \), but all of the distribution functions show large non-Gaussian effects for both large and small distances.

The scaling behavior at small \( r \) has been calculated by des Cloizeaux \(^{18}\) for an infinitely long excluded volume chain using renormalization group techniques. He finds that

\[ g_{ij}(r) \propto r^{\theta_{ij}}, \quad r << <R_{ij}> \]  

(4.7)

The exponent \( \theta_{ij} \) depends on the placement of \( i \) and \( j \) in the chain. If the results of the renormalization calculation apply to our bead chain then the scaling relationship (4.5) may not be correct at small \( r \). For three limiting possibilities the predicted exponents are:

\[
\theta_{ij} = \begin{cases} 
0.272 \pm 0.004 & i=0 \ j = N \\
0.459 \pm 0.003 & 0=i< j << N \\
0.71 \pm 0.05 & 0< i< j << N 
\end{cases}
\]  

(4.8)

Figure 4 is a log-log plot of the short distance behavior of \( g_m(r) \) for several values of \( m \). We find that each \( g_m \) has an exponent of about 0.25. This is particularly evident as \( m \to N \). Since we are
averaging over pairs with constant chemical distance, the exponent will tend to be that given by the minimum of the exponents of the different pairs which according to eq. (4.8) is that associated with pairs one of whose members is near the end. There is no evidence however in our data of the much larger exponents in eq. (4.8). A more extensive Monte Carlo calculation involving much larger chains would be useful.

The large $r$ behavior of the end to end distribution on the lattice has been examined using Monte Carlo by Domb$^{19}$ et al., Fisher,$^{20}$ McKenzie and Moore,$^{21}$ and des Cloiseaux$^{18a}$ have presented scaling arguments for the following form

$$g_{1N}(r) \propto R_N^{-3} \left( r/R_N \right)^{0.33} \exp\left(-\left( r/R_N \right)^{2.50}\right), r \gg R_N = \langle R_{ON}^2 \rangle^{1/2}$$

(4.9)

Our results are not precise enough to check Eq. (4.9) quantitatively but they do exhibit a significant deviation from a gaussian (cf.fig(3)). They also indicate that whatever scaling law does apply will describe near as well as distant bead pairs. A recent study$^{10c}$ of strongly stretched continuum chains showed asymptotic behavior for large $r/R_N$ as in Eq. (4.9) with an exponent of about 2.5.

The structure or scattering function is the Fourier transform of the total pair correlation function $g(r) = N^{-1} \sum_{i<j} q_{ij}(r)$

$$S_N(k) = \frac{1}{N} \sum_{j=1}^{N} e^{ik \cdot r_j}$$

(4.10)

Shown in Figure 5 is $S(k)$ versus $Q = kN^{0.6}$ for various values of $N$. It is seen that there is a universal behavior for $1/k$ greater than a bond distance. The $S(k) \sim k^{-5/3}$ behavior for $Q \gtrsim 2$ is in accord with Edwards$^{22,23}$ prediction of $g(r) \sim r^{-4/3}$ for $r \sim N^{0.6}$
5. **Dynamic Properties**

In this section we present various time dependent properties of the single polymer chain. We find that these properties have a scaling behavior in time. That is, the times involved in various large scale motion of the polymer are independent of the number of monomers when properly scaled. The scaling factor can be easily determined since the diffusion of the center of mass qualifies as a large scale motion. Let $t_G$ be the time it takes for the center of mass to diffuse an amount equal to the radius of gyration. From equations (3.7) and (4.2) this will equal:

$$t_G = \frac{0.05}{D} N^{2v+1} \quad (5.1)$$

To observe universal behavior we must express all times in terms of $t_G$.

Time dependant properties are commonly described in terms of correlation functions. If $H(t) \equiv H(R(t))$ is some function of the polymer chain configuration $R(t)$ then define:

$$C(t;H) = \frac{<H(t_0)H(t_0+t)>-<H(t_0)>^2}{<H(t_0)^2>-<H(t_0)>^2} \quad (5.2)$$

The averages are over an equilibrium distribution of initial values $R(t_0)$. This is represented in our simulations as an average over $t_0$ of one or several independent runs. The scaling behavior of the kinetics then requires that if $H(R)$ measures a global property
of the polymer then for large $N$, $C(t^{\alpha} N, H_N)$ should be independent of $N$ where $\alpha$ is a universal exponent.

In our earlier note we presented results for the autocorrelation functions of the end to end vector, the eigenvalues of the mass tensor, the radius of gyration and the intermediate scattering function. Here we wish to compare those results with some recent work by Kranbuehl and Verdier on a dynamical lattice model, and then to present new results on the viscosity of the polymer chain and the relative motions of beads in the chain.

5.1 Kinetic Scaling in Continuous and Lattice Models

As noted in ref. 3, we assumed the validity of scaling and then calculated, with a nonlinear least squares procedure, the best value for the scaling exponent $\alpha$ (see Appendix A). Using the ten autocorrelation functions examined and chain lengths ranging from 5 to 63 we then obtained $2.04 < \alpha < 2.24$ with a typical statistical error of 0.04. We believe that the difference between the values of $\alpha$ as given by the least squares fit are due primarily to the small chain lengths in our simulations and that $\alpha$ is indeed universal and close to $2\nu + 1$.

This result, while in satisfying agreement with various theoretical computations disagreed strongly with the results given in ref.5 on the time evolution of a lattice model of a polymer chain with excluded volume in which the relaxation time appeared to increase much faster with $N$. (Note that in the absence of any excluded volume both lattice and continuum models show behavior in which time scales as $N^2$).
Following our work, Kranbuehl and Verdier\textsuperscript{12} carried out new simulations of a dynamical lattice model. Unlike earlier work in which the configuration of the lattice polymer could change by either one or two bead moves alone, the new simulations permitted at any step either one or two bead moves with the relative fraction of two bead moves equal to $p$. Although this mixture of moves does indeed allow the excluded volume chain to relax much quicker than with just one type of move, their data for the largest values of $N$ (63 beads) still appear to show a slowing down of the relaxation times by a factor of $N$, which is similar to that found with the more restricted lattice dynamics.

Given this situation, it seems worthwhile to find ways of making direct comparisons between the lattice model and our model. This requires in particular that we have a consistent time scale in both models. To do this we note that in continuous space, without hydrodynamical interactions, the diffusion constant is independent of the internal potential energy, while in the lattice model it may depend both on the potential and on the dynamical rules (e.g. upon the value of $p$). We therefore propose that the unit of time in the two models be defined as the number of computer cycles needed for the mean squared displacement of the center of mass to equal a fixed multiple, say 6, of the mean squared end to end distance. There are sufficient data given in ref.\textsuperscript{12} to determine $t_{2,N}$, the half time of the correlation function for the end to end vector defined as

$$C(t_{2,N}; R_{1N}) = 1/2.$$  \hfill (5.3)
Assuming that only one exponential has survived in the correlation function we find that for the lattice model in the units of time defined above this half time is:

$$\tau_{2,N}^L = \frac{R_{1N}^2 \ln(2a_{p,N})}{D_{p,N} \tau_p}$$

(5.4)

where $a_{p,N}$, $\tau_p$, and $D_{p,N}$ are defined in ref. 12. For our model this half time will be given by

$$\tau_{2,N}^C = \frac{D \tau_{2,N}^N}{N R_{1N}^2}$$

(5.5)

These quantities are plotted in Figure 6 for the two models. The most important feature to note is that these two quite different models give roughly the same ratio (about 30 to 50) of rotational relaxation to diffusional motion. Secondly, for our model and for the lattice model with 3 different values of $p$ this ratio of times for large $N$ appears to be constant although we cannot be too certain of this, given the rather large error bars on the present calculation. Viewed from this perspective, the lattice model computations are not as inconsistent with the generally accepted scaling behavior of time dependent polymer properties as they seem. It would be useful to check further this question of scaling. This can be done in our model by simply increasing the length of the simulation. For the lattice model a variety of correlation functions should be examined to see if the situation of figure 6 obtains for all such functions.
5.2 Viscosity of Polymer Chains

We computed the autocorrelation function of the stress tensor \( J_{xy} \). Its Fourier transform gives the increase in the linear response to a shear wave of the chain plus solvent over the response of the pure solvent, i.e., the intrinsic viscosity.\(^8\)

\[
[\hat{n}(\omega)] = \frac{J_{xy}^2}{N} \int_0^\infty dt \ e^{-i\omega t} C(t; J_{xy})
\]

\[
J_{xy} = \sum_{i=0}^{N} x_i \ \frac{\partial U}{\partial y_i}
\]  
(5.6)

Shown in Figure 7 are log-log plots of \( C \) for various values of \( N \). In the Rouse model one can show that \(^{13,24}\)

\[
\lim_{N \to \infty} C(t; J_{xy}) = e^{-8t} I_0(8t)
\]

\[
= \frac{1}{\sqrt{16\pi t}} + o(t^{-3/2})
\]  
(5.7)

where \( I_0 \) is a modified Bessel function. Our data for the excluded volume chains appears to show the same \( t^{-1/2} \) dependence for times less than the slowest relaxation modes of a finite chain and an exponential decay for larger times.

There exists a sum rule relating the static or zero-frequency viscosity to the radius of gyration,\(^8\) namely

\[
[\hat{n}(0)] = \frac{J_{xy}^2}{N} \int_0^\infty dt \ C(t; J_{xy}) = G^2/6
\]  
(5.8)
The relevant numbers are given in Table II. It is seen that there is agreement to within 40%. It should be noted that the calculation of the integral in (5.8) is difficult from computer simulations since only a single number is obtained from each configuration and that number fluctuates greatly as the system evolves.

5.2 Relative Motions of Beads

Finally, we have calculated the autocorrelation functions describing how a single bead moves with respect to the center of mass and how pairs of beads move, i.e. \( C(t; r_i - \bar{z}) \) and \( C(t; r_i - r_j) \). Shown in figure 8 and 9 are autocorrelations of these functions for a chain of length 20. Consider the first of these, namely \( C(t; r_i - \bar{z}) \). It should decay in a time characteristic of the time it takes the ith particle to diffuse around the center of mass. Particles near the center of the chain are of course located nearer to the center of mass as shown by the function \( \langle (r_i - \bar{z})^2 \rangle \) plotted in figure 8. The half time and integral of \( C(t; r_i - \bar{z}) \) do show a deep minimum at the middle of the chain. However near the ends of the chain the situation is quite different. The ends appear to be much more mobile than beads located in the interior of the chain. One can detect a region of the chain, comprising about 15\% of each end of the polymer, where the diffusion time about the center of mass decreases as the distances to the center of mass increases. The ratio of the half time to the integral of the correlation function expresses how nearly exponential is the decay of the correlation function. Near the ends this ratio equals (within statistical errors) the exponential value \( \ln(2) \) but it
is lower near the middle of the chain. We interpret this to mean that the motion at the end of the chain has a single slow characteristic time scale. Near the center, in addition to this slow mode which will always dominate at long times, the motion is complicated by other, faster modes associated with motions about the center of mass. In Figure 9 is shown $C(t;\vec{r}_i-\vec{r}_j)$ for $N = 20$. The lines connect points of constant $i-j$. Thus this figure is the dynamical analogue of figure 2. Although edge effects are not very important for static correlation functions, dynamically they are much more important, correlation times decreasing by a factor of two if the pair of particles happen to be located near the ends.

Appendix A Calculation of the Scaling Exponent

In this appendix we give in detail the procedure we have used for calculating the scaling exponent, $\alpha$, which brings several time dependent correlation functions into agreement. With the trajectory generated by the simulation we calculate the correlation function $C(t; H_N)$ of some property $H$ for several values of $N$, using equation (5.2). The averages are taken over the entire length of the trajectory. This correlation function will depend upon the initial conditions and will fluctuate from run to run because of the finite time available for computing the average. Zwanzig and Ailawadi$^{25}$ have proposed that the variance of the estimate of the correlation function has the following form:

$$V(t,N) \equiv \langle (C-\langle C \rangle)^2 \rangle = \frac{4\tau}{T} \langle (1-\langle C \rangle)^2 \rangle \quad (A.1)$$

where $\tau = \int_0^\infty \text{d}t \ C(t; H_N)^2$ and $T$ is the length of the trajectory.

Our data verify their prediction within a factor of two.

Let us assume that the scaling hypothesis is valid, namely that there exists an $\alpha$ such that $C(sN^\alpha; H_N)$ is independent of $N$ as a function of scaled time $s$. Then the linear combination

$$\hat{C}(s, \alpha) = \frac{\sum_N w(t,N)C(sN^\alpha; H_N)}{\sum_N w(t,N)} \quad (A.2)$$

will equal the scaled correlation function. To minimize the variance of the estimate of $\hat{C}(s, \alpha)$, the weights $w(t,N)$ must be chosen so that each term in the linear combination contributes an equal variance. This implies:
\[ w(t,N) = \frac{1}{\mathcal{V}(t,N)} \quad (A.3) \]

The success of the scaling hypothesis can then be judged by the squared difference between the scaled averaged function and the original data:

\[ \chi^2(\alpha) = s_0^{-1} \int_0^{s_0} ds \sum_{N} \frac{(C(sN^\alpha; H_N) - \hat{C}(s,\alpha))^2}{\mathcal{V}(sN^\alpha, N)} \quad (A.4) \]

The best scaling exponent is that which minimizes \( \chi^2(\alpha) \). In the integral in equation (A.4) we have chosen \( s_0 \) to be such that for at least two values of \( N \), \( C(sN^\alpha; H_N)^2 > \mathcal{V}(sN^\alpha, N) \), i.e. the signal is greater than the noise.

The advantages of the above procedure are that it make no assumptions about the form of \( \hat{C}(s) \), that all of the available data is used with the proper statistical weight, and that the procedure is stable (i.e., a minimum in \( \chi^2(\alpha) \) is ensured).

The excess viscosity $[\hat{\eta}(0)]$ as a function $N$, the number of beads per chain. The relationship (equation 5.8) asserts that $[\hat{\eta}(0)]$ should equal $G^2/6$. The agreement with our data is good only to about 40%, probably because of the large fluctuations in $J_{xy}$ and because of the difficulty in performing the time integral. To check our program we have calculated $<(VV)^2>$ and $<V^2U>$ which must be equal if averaged over the Boltzman distribution. Also shown is $<J_{xy}^2>$ and $\tau_m$, the upper limit used in the time integral in eq. 5.8.
Figure Captions

Figure 1: The mean squared end-to-end distance (dashed line) and the mean radius of gyration (solid line) versus the number of particles.

Figure 2: The average values of four moments of $R_{ij}$ versus the relative distance, $x$, from the center of the chain for a chain with 20 beads where $x = (i+j-2)/19$. The lines connect points of constant chemical distance ($i - j = \text{constant}$). The vertical axis is in units of $<R_{1,20}^M>^{1/M}$. Hence the bottom of the tree represents moments of adjacent beads.

Figure 3: The logarithm of the pair distribution function for beads $i$ and $j$ on a chain with 63 beads, as a function $r^2/r^*2$ where $r^*2 = <R_{ij}^2>$. The distributions are averaged over all $i$ and $j$ that satisfy $i - j = m$ where $m = 5$ for ---; $m = 10$ for -----; and $m = 40$ for (-----) the straight line(-----) is the corresponding curve for the ideal chain (no excluded volume interaction).
Figure 4: The probability distribution \( g_{ij}(r) \) versus \( \log (r/r^*)^2 \) for small \( r \). The distribution are averaged over all \( i \) and \( j \) such that \( i - j = m \) for a chain consisting of 48 beads. Three values of \( m \) are shown (5, 20 and 40) which are represented by (○, ●, ◆) respectively. The line is the curve \( g(r) = a r^{-1/4} \).

Figure 5: \( S_N(k) \) versus \( q \) where \( q = kN^{-\nu} \) and \( \nu = 0.6 \). The symbols represent the results of six different values of \( N \) (see right-hand scale). The line is \( 0.3Q^{-5/3} \). For large \( k, S(k) \rightarrow l/N \). It is seen that for \( k < 2 \) the curves coincide.

Figure 6: The ratio of the half time of the correlation function of the end-to-end vector to the mean time for the center of mass to diffuse a distance equal to the radius of gyration as a function of the number of beads. The present calculation is shown as (I) and the dynamical lattice simulation (ref.12) with 3 values of \( p, (1.0, 0.5, 0.0) \) represented by (●, ○, ◆) respectively. \( p \) is the fraction of two bead moves in the lattice model.
The logarithm of the autocorrelation function of the stress tensor versus log(t). The straight line is for an infinitely long Rouse chain (no excluded volume) which behaves asymptotically as \( t^{-\frac{3}{2}} \). The other five lines are fits to the simulation data for excluded volume chains, from left to right of lengths 5, 10, 20, 33, 48.

The relaxation time of a single bead about the center of mass for a chain of length 20 as a function of \( x = (i - 10)/10 \). The solid curve is \( \langle (\vec{r}_i - \vec{z})^2 \rangle \), the average square distance from the center of mass. The mean correlation time, defined as \( \int dt C(t; \vec{r} - \vec{z}) \), is plotted as (-----). The half time of the correlation function (when \( C(t_{1/2}; \vec{r}_i - \vec{z}) = \frac{1}{2} \)) is plotted as (-----). The halftime for the correlation function \( C(t; \vec{z}_i - \vec{z}_2; 1 - i) \) is given by (-----).

The halftime for the correlation function \( C(t; \vec{z}_i - \vec{z}_j) \) plotted against \( x = (\text{see figure 2}) \) for a chain with \( N = 20 \). The lines connect points of constant \( M = i-j \). M is given on the right hand scale. This is the dynamical analog of figure 2.
